Abstract- Estimation of individual and population slopes using Linear Minimum Variance Unbiased Estimation by Wu and Bailey (1988) is applied for incomplete longitudinal studies. In these studies the right censoring process is considered informative, in which the number of observations made for each subject is assumed to vary depending on the rate of change or slope of the individual response variable. This process of ‘missing not at random’ poses problems in the estimation of the slope parameters. The proposed method provides better estimates under different parametric models for the censoring distribution. The method’s performance is studied through a simulation study under Standard Normal and Uniform censoring distributions.

Index Terms- Cumulative distribution function, Empirical Bayes estimation, Standard Normal distribution, Probit function, Informative Right censoring, Simulation.

I. INTRODUCTION

Characterization of rate of change in the study variable over time is of primary interest in longitudinal studies, where repeated measurements of the study variables are taken on the subjects. The rate of change of these variables over time is one of the primary interests of the researchers, as it helps us track the individuals who are at risk or those who need immediate attention. The classical methods of estimation fail under the condition of ‘missing not at random’ or when the censoring distribution is dependent on the rate of change of the study variable of the individual subject. Longitudinal studies prolong for many years and entail dropouts due to deaths, migration and related factors. There are several proposed methodologies to accommodate incomplete data by Orchard and Woodbury (1982), Kleinbaum (1973) and Laird and Ware (1982). These methods assume patterns that accommodate dropouts that are independent of the study variable. In this paper, the pattern of missing data considered is related to the study variable.

The term ‘informative right censoring’ in the context of slope estimation refers to the situation where the censoring probability of each individual relates to his or her underlying rate of change (Wu and Bailey, 1988). They showed that under a linear random effect model the weighted least square estimate of slope can be severely biased if the right censoring process is informative, although it is most efficient if the censoring process is non-informative. In an effort to reduce the bias introduced by the presence of informative right censoring, Wu and Carroll (1988) derived a Probit Pseudo-Maximum Likelihood Estimator (PPMLE) of the population rate of change under a linear random effect model where the right censoring process follows a probit function, both of initial value and of the slope of the individual subjects. Wu and Bailey (1989) adapted a conditional linear model approach and proposed a Linear Minimum Variance Unbiased (LMVUB) and Linear Minimum Mean Square Error (LMMSE) estimators of the population rate of change, which they showed were competitive with the PPMLE in their simulation study. The present study focuses the effectiveness of the LMVUB estimator under different censoring distributions, whose parameter depends on the rate of change of the individual study variable. LMVUB estimator is compared with the general Empirical Bayes estimator, Un-weighted and Weighted estimators. To measure its effectiveness, the study considers both the individual and population slopes. Simulation results are considered and inferences are made, with suggestions for the future research.

II. THE ESTIMATION PROCEDURE

The LMVUB estimator is derived from the general case of the Empirical Bayes estimation procedure. This model assumes that here are n subjects and that for each subject i (i = 1, 2, ... , n) the following conditions hold:

(i) \( b_{i, ols} | \beta_1, t_{im_i} \sim N(\beta_1, V_i) \)

(ii) \( \beta_i | \gamma_0, \gamma_1, t_{im_i} \sim N(\gamma_0 + \gamma_1 * t_{im_i}, A) \)

where \( b_{i, ols} \) is the Ordinary Least Square (OLS) estimate of the slope and \( t_{im_i} \) is the maximum time the \( i^{th} \) subject is followed up.

\[ V_i=\text{Var}(b_{i, ols})=\frac{\sigma\epsilon^2}{\sum_{j=1}^{m_i}(t_{ij}-\bar{t}_i)^2}, \text{ where } \sigma\epsilon^2 \text{ is a known constant} \]

and \( A= \text{Var}(\beta_i) \) is also assumed to be known. Let \( (t_{i1}, t_{i2}, t_{i3},...,t_{im_i}) \) denotes the vector of time points for the \( i^{th} \) subject. It is assumed that the last measurement time, \( t_{im_i} \) is the
The marginal distribution of $b_{i,ols}$ is given by

$$b_{i,ols} | \gamma_0, \gamma_1, t_{im} \sim N(\gamma_0 + \gamma_1 t_{im}, A + V_i)$$

where $\gamma_0$ and $\gamma_1$ are the parameters of the censoring distribution.

The posterior distribution of $\beta_i$ given $b_{i,ols}$ is

$$\beta_i | b_{i,ols}, \gamma_0, \gamma_1, t_{im} \sim N(\beta_i^*, V_i (1 - B_i))$$

where $\beta_i^* = (1 - B_i) b_{i,ols} + B_i (\gamma_0 + \gamma_1 t_{im})$, with $B_i = \frac{V_i}{V_i + A}$

$$\gamma = \begin{pmatrix} \gamma_0 \\ \gamma_1 \end{pmatrix}$$

Let

$$X' = \begin{pmatrix} 1 & 1 & 1 & \ldots & 1 \\ t_{im_1} & t_{im_2} & t_{im_3} & \ldots & t_{im_n} \end{pmatrix}$$

and

$$D = \begin{pmatrix} \frac{1}{V_i + A} & 0 & 0 & \ldots & 0 \\ 0 & \frac{1}{V_i + A} & 0 & \ldots & 0 \\ 0 & 0 & \frac{1}{V_i + A} & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ldots & \frac{1}{V_i + A} \end{pmatrix}$$

$$B = \begin{pmatrix} B_1 & 0 & 0 & \ldots & 0 \\ 0 & B_2 & 0 & \ldots & 0 \\ 0 & 0 & B_3 & \ldots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \ldots & B_n \end{pmatrix}$$

The parameter $\gamma$ is estimated using the Weighted Least Square (WLS) method and is given by

$$\hat{\gamma} = (X' DX)^{-1} X' DB$$

The Empirical Bayes estimate for the individual slope is given by

$$\hat{\beta}_{i,eb} = (1 - B_i) b_{i,ols} + B_i (\hat{\gamma}_0 + \hat{\gamma}_1 t_{im})$$

for $i = 1, 2, 3, \ldots, n$. Its matrix representation is given by

$$\hat{\beta}_e = (1 - B) b_{ols} + B X (X' DX)^{-1} X' DB$$

where $B_i = 1$ results in the LMVUB estimation.

The corresponding estimator of the population slope is

$$\hat{\beta}_{pop,eb} = \frac{1}{n} \sum_{i=1}^{n} \hat{\beta}_{i,eb}$$

The assumption of a conditional linear model is given by

$$b_{i,ols} | t_{im} = \tau_0 + \tau_1 t_{im} + \epsilon_{wi}$$

which $E(\epsilon_{wi}) = 0$ and $Var(\epsilon_{wi}) = \sigma^2_{\epsilon_{wi}}$

Then, $LMVUB(\beta) = \hat{\tau}_0 + \hat{\tau}_1 E(t_{im})$

If $\hat{B}_i = 0$, it reduces to the Unweighted estimator and its population slope is given by

$$\hat{\beta}_{w,eb} = \frac{1}{n} \sum_{i=1}^{n} b_{i,ols}$$

The weighted individual slope estimator is $\hat{\beta}_{i,w} = (1 - B_i) b_{i,ols} + B_i \hat{\beta}_{w}$ with the corresponding population slope estimator

$$\hat{\beta}_w = \frac{\sum_{i=1}^{n} (1 - B_i) b_{i,ols}}{\sum_{i=1}^{n} (1 - B_i)}$$

III. SIMULATION STUDY

The simulation study is carried out to compare the performance of the four estimators: Empirical Bayes, LMVUB, Weighted and Unweighted Estimators. The study compares both individual and population slopes. Simulations are carried out for a setting similar to that already proposed and discussed in the literature by Wu and Baily (1988). R software is used to perform the simulation process. Parameters used in the simulation are similar to those of Wu and Baily, who obtained the estimates from a feasibility study for an anti-photolytic replacement therapy trial conducted by the Workshop on the Natural History of Piz Emphysema. The study variable in this trial is rate of decline in the FFV measurements. We generated 1000 data set, each containing 100 observations, according to the following specifications:

- Measurement error standard deviation $\sigma_\epsilon = 155$; slope standard deviation $\sigma_\beta = 90$; the expected slope $\beta = -90$. It is assumed that the study duration extends to 3 years with 4 measurements for each year. Further it is assumed that right
censoring occurs only at the middle of each year, after the second measurement. The probability of right censoring or censoring distribution during a specified time interval \((0, t_j)\), given the slope \(\beta_i\) to be \(\Phi(\eta_{0j} + \eta_i \beta_i)\), where \(\Phi()\) is the cumulative probability distribution function of \(N(0, 1)\). The censoring parameter for different time intervals are denoted by \(\eta_{0j}, j = 1, 2, 3\). The simulations are carried out under 3 different conditions:

1. \(\eta_1 = 0.00, \eta_{01} = -1.41, \eta_{02} = -0.71 \) and \(\eta_{03} = -0.25\); (2) \(\eta_1 = -0.0113, \eta_{01} = -3.04, \eta_{02} = -2.04 \) and \(\eta_{03} = -1.38\); and (3) \(\eta_1 = -0.0138, \eta_{01} = -3.26, \eta_{02} = -2.26 \) and \(\eta_{03} = -1.60\); in the above scenario, the first set of parameters correspond to non-informative right censoring and the second and third conditions correspond to Informative right censoring. The simulation process is carried out with the following sequence.

1. \(\beta_i \sim \text{Normal}(-90, 91^2)\);
2. \(\Pr(T < t_j \mid \beta_i) = \Phi(\eta_{0j} + \eta_i \beta_i)\); and
3. \(b_{t, ols} \mid \beta_i, t_{im} \sim \text{Normal}(\beta_i, V_i)\), where

\[ V_i = \text{Var}(b_{t, ols}) = \frac{155^2}{\sum_{j=1}^{m_i} (t_{ij} - \bar{t}_i)^2} \]

The criteria used to evaluate the performance are bias and two types of Mean Square Error (MSE) defined respectively as:

\[
\text{Bias (a)} = \frac{1}{R} \sum_{r=1}^{R} \left( \hat{\beta}_r - \beta \right)
\]

\[
\text{MSE (a)} = \frac{1}{R} \sum_{r=1}^{R} \left( \hat{\beta}_r - \beta \right)^2
\]

\[
\text{MSE (b)} = \frac{1}{nR} \sum_{r=1}^{R} \sum_{i=1}^{n} \left( \hat{\beta}_{ir} - \beta_{ir} \right)^2
\]

where \(R\) is the total number of replications, and \(n\) is the number of observations in each data set. MSE (a) measures the closeness of the estimator to the population slope and MSE (b) measures the closeness of the estimator to the individual slopes.

### 3.1 Random Generation of Censoring Distribution:

The censoring distribution, corresponding to the random variable \(m_i\) is generated using the assumption \(\Pr(T < t_{ij} \mid \beta_i) = \Phi(\eta_{0j} + \eta_i \beta_i)\). Thus, the censoring distribution for each subject varies as \(\beta_i\) varies from subject to subject. As \(\Phi\) denote the cumulative distribution function of standard normal variate, the following procedure is used to generate \(m_i\) values.

1. Four observations are made in three years amounting to maximum \((m_i) = 12\)
2. Also it is assumed that right censoring occurs only at the middle of each year after the second measurement. This implies \(m_i\) takes values 2, 6, 10, 12.
3. For each of the three years the normal cumulative probabilities with varying \(\eta_{0j}\)
j= 1, 2, 3 are calculated.
4. The probability for \(m_i = 2\) is taken as the cumulative probability calculated for \(j = 1\). The probability for \(m_i = 12\) is taken as the difference between unity and the cumulative probability calculated for \(j = 3\). The probability for \(m_i = 6\) is taken as the difference between the cumulative probabilities for \(j = 2\) and \(j = 1\). The probability for \(m_i = 10\) is taken as the difference between the cumulative probabilities for \(j = 3\) and \(j = 2\).
5. In case of Uniform cumulative distribution function the upper and lower limits of the distribution are fixed by

\[
\text{Lower limit} = \text{Minimum} (\beta_i), \eta_1 + \text{Minimum} (\eta_{01}, \eta_{02}, \eta_{03})
\]

\[
\text{Upper limit} = \text{Maximum} (\beta_i), \eta_1 + \text{Maximum} (\eta_{01}, \eta_{02}, \eta_{03})
\]

The above procedure represents one of the ways of implementing

\[ \Pr(T < t_{ij} \mid \beta_i) = \Phi(\eta_{0j} + \eta_i \beta_i) \]

to generate random values for \(m_i\).

Simulation results corresponding to standard normal censoring distribution are provided in Table 3.1. This summarizes results regarding bias and mean square error. The result reveals, irrespective of Informative or Non-Informative right censoring process, the LMVUB performs better compared to the other three estimators. By observing the MSE corresponding to population and individual slopes, the LMVUB estimator has

the minimum MSE, followed by Weighted, Empirical Bayes and Unweighted estimators in that order. This trend is similar in both the population and individual slopes. Also to be noted is the magnitude of reduction in the MSE values. In case of Non-informative right censoring the MSE corresponding to the second best weighted estimator for population slope is nearly five times as that of the LMVUB estimator. In case of the individual slopes the MSE of Weighted estimator is 4.4 times as that of the LMVUB estimator.

Comparing the bias in all the three scenarios, it is seen that the Empirical Bayes estimator performs better than LMVUB estimator in cases with $\eta_1 = 0$ and $\eta_1 = -0.0113$. In case of $\eta_1 = -0.0138$, the bias of the LMVUB estimator is the minimum. In most of the estimators, it is seen that ‘over estimation’ of the parameters takes place.

In the presence of informative right censoring with $\eta_1 = -0.0113$, the LMVUB performs better compared to the other three estimators. The MSE has a similar pattern in this case, but with a reduced margin of the multiplicative factors. Considering the population slope the MSE of the second best weighted estimator is nearly 1.6 times as that of the corresponding LMVUB estimator. For the individual slopes the MSE of the weighted estimator is nearly 2.3 times as that of the corresponding LMVUB estimator.

Comparing the bias in all the three scenarios, it is seen that the Empirical Bayes estimator performs better than LMVUB estimator in cases with $\eta_1 = 0$ and $\eta_1 = -0.0113$. In case of $\eta_1 = -0.0138$, the bias of the LMVUB estimator is the minimum. In most of the estimators, it is seen that ‘over estimation’ of the parameters takes place.

Simulation results corresponding to the Uniform censoring distribution are provided in Table 3.2. In this case again, the dominance of LMVUB estimator can be seen in all but the case for population slope with $\eta_1 = 0$. By observing the MSE corresponding to population and individual slopes, the LMVUB estimator has the minimum, followed by Weighted, Empirical Bayes and Unweighted estimators in that order. This trend is similar in both the population slope and

| Empirical Bayes | 1.803  | 36202.530    | 1860.097       |
| LMVUB           | 3.215  | 1330.802     | 27.432         |

| \( \eta_1 = -0.0138 \) |        |              |                |
| Unweighted      | 22.441 | 62192.720    | 5227.073       |
| Weighted        | 18.884 | 39459.710    | 2548.442       |
| LMVUB           | 4.249  | 2499.359     | 20.384         |

as well in the individual slopes. Also, this pattern is similar to that of the one seen using the Standard Normal cumulative distribution.

In case of Non-informative right censoring with the population slope, the weighted estimator has the least MSE. The other three have marginally higher values. In case of the individual slopes the MSE of Weighted estimator is 5.9 times as that of the LMVUB estimator that has the minimum MSE.

In the presence of informative right censoring with \( \eta_1 = -0.0113 \), the LMVUB performs better compared to the other three estimators. Considering the population slope the MSE of the second best weighted estimator for the population slope is nearly 19.4 times as that of the corresponding LMVUB estimator. For the individual slopes, the MSE of the second best weighted estimator is nearly 66.6 times as that of the corresponding LMVUB estimator.

The scenario of informative right censoring with \( \eta_1 = -0.0138 \), the MSE of the population slope for the second best weighted estimator is nearly 15.8 times as that of the corresponding LMVUB estimator. For the corresponding individual slopes the MSE of the weighted estimator is nearly 125 times as that of the corresponding LMVUB estimator.

Comparing the bias in all the three scenarios, it is seen that the Weighted estimator performs better in the non-informative situation, Unweighted estimator performing better in case of informative right censoring with \( \eta_1 = -0.0113 \) and the LMVUB performing better in the case of \( \eta_1 = -0.0138 \). In the case of the Uniform censoring distribution for most of the estimators ‘over estimation’ of the parameter values takes place.

IV. DISCUSSION

Comparison with respect to the MSE under simulation study reveals the better performance of LMVUB estimator as an alternative to that of the Unweighted, Weighted and Empirical Bayes estimators in both the informative and Non-informative Right censoring scenarios. LMVUB estimator performs better in estimating both individual and population slopes. This advantage of LMVUB may be the result of the conditional linear modelling of the observed slopes with the censoring time that provides a better judgement of the rate of change in the response variable. As Little (1988) pointed out in the context of conditional linear models, the main idea of the Empirical Bayes estimator adapted here is to shrink not towards a common mean but towards a regression line where the mean is a linear function of the censoring time.

The comparison with respect to the Standard Normal cumulative and Uniform distributions indicates the effectiveness of LMVUB in the changing pattern of the dropouts. In case of the Uniform distribution the dropouts are spread in a more even manner compared to that of the Normal distribution that has a monotonic dropout pattern. LMVUB is capable of accommodating both the patterns and has minimum MSE in both
the scenarios. Wu and Bailey (1989) show that the conditional expectation of the slope, given the censoring time, is a monotonic function of the censoring time under the linear random effects model with probit censoring distribution.

Further theoretical work is necessary in the areas of testing the presence of informative right censoring. This requires estimating the standard errors for the population and individual slopes. The case when the variance parameters are unknown needs to be addressed separately. Subjects with one observation need to be accommodated, may be using other than slope construct, to fully utilize the available information.
