Food Dyes Decolourized by *pleurotus ostreatus*

Anthony Au, Fazreen Dzulkafli

Faculty of Biotechnology & Life Sciences, UNISEL, Malaysia

Abstract- This study employed a comprehensive approach to testing the capability of *P. ostreatus* in decolourising four different food dyes and to investigate the bio-adsorption properties of *P. ostreatus* under the equilibrium state. Decolourisation of Carmoisine Red, Tartrazine Yellow, Brilliant Blue FCF and Fast Green FCF were determined by UV-visible spectrophotometric method. Present study had confirmed that *P. ostreatus* provided almost complete decolourisation of 10ppm food dyes. Dried *P. ostreatus* along with agitation have a higher efficiency, efficacy and capability during the dye decolourisation. As high as 81.34% for Carmoisine, 45.36% for Tartrazine, 19.82% for Brilliant Blue FCF and up to 28.99% for Fast Green FCF were determined by UV-visible spectrophotometric method. The interpretation of results had shown the maximum capacity (Qm) of *P. ostreatus* which range from 0.05 to 0.43mg/L in dyes decolourisation. Our data were adequately fitted to Langmuir isotherm and subordinate to Pseudo second kinetic order. Colourless solution of Carmoisine Red was visually transformed by *P. ostreatus* within 5 days of dye treatment.

Index Terms- *Pleurotus ostreatus*, food dye, decolourisation, fresh biomass, dried biomass

I. INTRODUCTION

Dyes have been increasingly applied in the industries of cosmetics, textile, manufacturing, and food. With the high stability to light, temperature and resistance to microbial attacks, a range of cost-effective and colourful synthetics food dyes can be manufactured in pilot scale to sustain the limited choice of natural food dyes (Kiseleva et al., 2002).

The synthetics food dyes are make up of complex aromatic molecular structures of azo and phenylmethane groups, which are recalcitrant xenobiotic compounds, that resistance to environmental decolourization process (Fu and Viraraghavan, 2001). Thus, leaving the unsolved environmental problem to biologists and public.

Chemical and physical wastewater treatments have been widely practiced for the past decades compare to biological approach. Most of the physical approach, however, simply accumulate and concentrate wastewater, left over carcinogenic solid waste (food dyes), that further impede disposal problem. Expensive chemical approach using peroxide or ozone is inapplicable to schedule food industrial wastewater treatment.

To fill in the gap, biological approach using fungi to treat wastewater has received much attention recently. The white rot fungi have proven its capability to degrade synthetic chemicals, such as azo dyes from textile industry (Zhao and Hardin, 2007). The plausibility was this fungi secrets ligninolytic enzyme to degrade complex molecular structure of the synthetic dyes; thus, it was an alternative to the existing approach (Selvam et al., 2003).

To date, vast majority of fungal strains have involved in biological decolourization approach. There were *Aspergillus spp.*, *Fusarium*, *Phanerochaete chrysosporium*, *Trametes versicolour*, *Coriolus versicolour*, *Cunninghamella polymorpha*, *Funalia trogii* and *Rhizopus arrhizus*, *Rhyzopus oryzae*, *Cyathus bulleri*, *Laetiporus sulphureus*, *Stereomyces sp.*, *Trametes versicolour*, *Polyporus elegans*, *Trametes versicolor*, *Lentze betulina*, *Mucor mucedo*, *Phanerochaete sordida*, *Pycnoporus sanguineus*, *Trametes elegans* (Da-Re and Papinutti, 2011; Erum and Ahmed, 2010; Moturi and Singara-Charya, 2009; Seyis and Subasioglu, 2008; Erkut et al., 2007; Nigam et al., 2000)

*Pleurotus ostreatus* (*P. ostreatus*), is widely available, an edible mushroom for food industry. However, not much attention has been raised for its decolourization ability. This research is to source out the capability, efficacy and efficiency of *P. ostreatus* in decolourizing the food dyes, indirectly contributing knowledge to wastewater treatment in food industries.

II. MATERIALS AND METHODOLOGY

A. Microorganism and Dye Preparation

Fresh *P. ostreatus* bodies were purchased from TESCO Shah Alam, Malaysia. The unlived *P. ostreatus* biomass was dried in the incubator (30°C; overnight) after removed its stipe. Potato Dextrose Agar (PDA) and Potato Dextrose Broth (PDB) (Fluka, Sigma-Aldrich USA) were prepared followed by autoclaving (121°C, 20mins).

*P. ostreatus* was cultures on PDA. Active mycelium was cut and was transferred to Universal bottles containing 10ml of PDB and incubated at 28°C. Prior to sterilization by autoclaving, the medium was adjusted to pH 6.5 with 20mM acetate buffer. After 3-5 days, the inoculum of each bottles were homogenized.

Four different colour dyes (Nona, Malaysia) were selected and each of their unique properties was further described in Table I.

B. Decolourization Assay

Dye decolourization assay was started on Petri dishes (3 parallel) with different parameter of dyes after inoculated with mycelial plugs cut from actively growing mycelia. Another 3 parallel of *P. ostreatus* that cultivated in the liquid medium was decolourized with the respective dyes. Inoculated universal bottles with the same medium without dye served as control.

C. Adsorption Isotherm and Kinetics Studies

Adsorption studies were carried out by dissolving 10ppm (part per million) of dye. The 5, 10, 50g/L of *P. ostreatus* gills (fresh and dried) were xthoroughly with different concentration of dyes and the suspensions were shaken (150rpm) at room temperature.

D. Spectrophotometric Analysis

Samples of 1.0 mL were collected from the duplicate flasks and were centrifuged for 10,000rpm for 5 min. The residual dyes concentration in the solutions were measured by Hitachi UV-vis U1900 spectrophotometer at required time intervals 1, 6, 24, 48, 72, 96 and 120 hours. Decolourisation was determined by monitoring the absorbance at the wavelength maximum for each dye as shown in Table I.

III. RESULTS

A. Fungal Morphology and Decolourization Ability

For the spore decolourization studies, the decolourization rate of respective strains was not as efficient as compared to the bioabsorption studies. Fresh and dried gills of *P. ostreatus* showed its capability in both decolourisation and adsorption. However, cultured media condition may be the pitfall for the effectiveness of the cultured *P. ostreatus* dye adsorption activity (Seyis and Subasioglu, 2008). Dye degradation is improved by the active enzymes encoded in *P. ostreatus* biomass (Neelamegam et al., 2004). Therefore, we will emphasis on the biomass usage that is more advantageous in decolourisation studies.

Decolourization assay was chosen on 4 commercially important dyes, with a wide range of applications across the household and food industries. Decolourization in dyes solution was assessed by visual disappearance of colour and reduced in absorbance reading after 5 days. Carmoisine, Tartazine Yellow, Brilliant Blue FCF and Fast Green FCF were decolourized by 0.1g of fresh *P. ostreatus* with a percentage of 30.49±1.3, 12.66±1.2, 5.11±0.2 and 10.43±0.3% respectively (Figure 1). Meanwhile, dried *P. ostreatus* was significantly decolourized the Carmoisine (77.83±0.9) and red colour was visually disappeared on the fifth days. Tarzine showed 36.45±1.1 % of dye decolourization its appearance was transformed to light yellow. Decolourization of Brilliant Blue FCF (16.21±0.3%) and Fast Green FCF (21.85±0.5%) were also achieved by 5g/L of dried *P. ostreatus*. Figure 1 illustrated the greater decolourisation efficacy for dried biomass than those of fresh biomass in our study.

Percentage for dye decolourization was calculated according to the formula:

\[ D(\%) = \left(\frac{C - S}{C}\right) \times 100\% \]

where

- C -- absorbance of dye in a control sample,
- S -- absorbance of dye in samples

Fig. 1 Total percentage of dyes (R= Carmoisine Red, Y= Tartazine Yellow, B= Brilliant Blue FCF, G= Fast Green FCF) at 10ppm decolourized by 5g/L dried and fresh *P. ostreatus* biomass after 120 hours treatment

B. Effect of Agitation

Shaking at 150rpm, all dyes decolourization was enhanced gradually with the passage of time. After 5 days of treatment, 5g/L of fresh *P. ostreatus* biomass has decolourized 5.72%, 3.8%, 2.1% and 1.59% with respect to Carmoisine, Tartazine Yellow, Brilliant Blue FCF and Fast Green FCF. Agitation has an effect on the dried *P. ostreatus* decolourization efficiency, the percentage of dye adsorption increased to the maximum of 3.51% (Carmoisine), 8.91% (Tartazine), 3.07% (Brilliant Blue FCF) and 7.15% (Fast Green FCF).

C. Langmuir Equilibrium and Adsorption Isotherm

The capability of *P. ostreatus* in colour dyes absorption was demonstrated in Table II. The amount of adsorption at equilibrium, \( q_e (mg/g) \), was calculated using following formula (Santhi et al., 2010; Hameed et al., 2008; Islek et al., 2008):

\[ q_e = \frac{(C - Ce)W}{V} \]

where

- \( q_e (mg/g) \) -- amount of dye adsorbed by *P. ostreatus* biomass at equilibrium state,
- \( C_0 \) and \( C_e (mg/L) \) -- the initial and equilibrium liquid phase concentration of dye
- \( V (L) \) -- total volume of dye solution,
- \( W (g) \) -- weight of the biomass

Table II Total bio-adsorption \( q_e \) of *P. ostreatus* (Sample Dosage: 5g/L, Dye Concentration: 10mg/L, Speed of Stirring: 150rpm, room temperature)

Adsorption Isotherms is to investigate the association between the adsorbate concentration and the amount adsorbed on the absorbent at the constant rate. Langmuir Isotherm equation value was given in Table III. The equation may be expressed as (Vijayakumar et al., 2012; Santhi and Manonmani, 2009):

$$\frac{C_e}{q_e} = \frac{1}{kQ_m} + \frac{C_e}{Q_m}$$

where

$Q_m$ (mg/g) -- maximum adsorption capacity, slopes
$k$ -- Langmuir constant

From the graph of $C_e/q_e$ vs $C_e$, we can calculated where $Q_m$ equal to slope $(1/Q_m)$ and value of $k$ is intercepts $(1/kQ_m)$ of linear plots.

D. Lagergren’s Pseudo-First Order Kinetics Analysis

Kinetic studies of adsorption were carried out in different contact time to the surface of P. ostreatus. The amount of dye absorbed were increase with the passage of time. Referring Vijayakumar et al. (2012), the amount of adsorption $q_t$ (mg/g) was calculated by

$$q_t = \frac{(C_0 - C_t)V}{W}$$

Figure 2 and 3 represent the bio-adsorption model for Pseudo first and second kinetics order respectively. The high values of correlation coefficients in our data (Table IV) proved the kinetics of bioabsorption are obeying pseudo-first-order rate kinetic model.

The kinetic data were acquired from the Lagergren’s pseudo-first order rate equation (Kumar et al., 2010; Santhi and Manonmani, 2009):

$$\log(qe - q_t) = \log qe - \frac{k_1(t)}{2.303}$$

where

$k_1$ -- first order rate constant, obtained from the slopes of the linear plots of log $(qe - q_t)$ vs $t$

The linear form of pseudo-second-order kinetics described as (Kumar et al., 2008; Hameed et al., 2008):

$$\frac{t}{q_t} = \frac{1}{k_2qe^2} + \frac{1}{q_e(t)}$$

where

$k_2$ -- second order constants rate in (g/mg h), obtained from the slope and intercept of plot $t / q_t$ vs $t$

IV. DISCUSSION

Dead P. ostreatus with the amount of 20g/L showed an excellent dye decolourization characteristic with an increasing surface area for adsorption as a consequence of cell rupture upon death. Increase dyes exposure on fungal cell wall that covers with chitin or chitosan is the major site of biosorption, for example the pileus (Vetter, 2007). Apart, researchers have also reported that dead biomass was better choices that can effectively adsorbing organic pollutants and dyes compare to live biomass (Maurya et al., 2006; Seyis and Subasioglu, 2008).
disappearing of dyes (measure by visual appearance) was due to the chromophoric group transformation either by metabolism and adsorption of \textit{P. ostreatus}. (Zhao, 2004) \textit{P. ostreatus} biomass shown its highest capability and efficiency to adsorb and decolourize Carmoisine which contains monoazo group. Phenols structure in Carmoisine is easy to oxidize to phenoxyl radicals by laccase in the presence of O$_2$ cofactor (Couto, 2009). Similarly, monoazo group of Tartrazine, which owned a simple molecular structure and light molecular weights has successfully been decolourized by \textit{P. ostreatus} biomass. High laccase activity has reported in the decolourization of Direct Dye Solar Golden Yellow R under optimized condition (Jilani et al., 2011). The Naphthyl compounds can be decolourized to Naphthoquinone by \textit{P. ostreatus} (Zhao, 2004). All the bonding and structure (azo, phenolic and naphthalene) can react by \textit{P. ostreatus} and produce uncoloured compound after metabolism thus it appeared translucent (Yiping et al., 2008). However, Brilliant Blue FCF with the high molecular weight and complex molecular structure are more resistant to be decolourized by \textit{P. ostreatus}. Fast Green FCF also has similar instance with Brilliant Blue FCF, thus representing the Triphenylmethane dye group that contained complex molecular structure and large molecular weight is steric hindrance and resist food dyes to bind. The steric hindrance occurs due to the large molecular size and consequently caused it resistant to be transformed or degraded into simpler structure. Faraco et al. (2009) has reported in the presence of complex poly-azo and a stilbene structure in dye wastewater was unable to be degraded by the laccases of \textit{P. ostreatus}. The chromophoric group did not transformed by \textit{P. ostreatus}, thus the colour still can be visualized. All of these four dyes contain sulfonate groups can be decolourized by \textit{P. ostreatus} (Lu et al., 2008).

V. CONCLUSION

As the result, the low cost edible \textit{P. ostreatus} can act effectively toward monoazo group of food dyes for Carmoisine and Tartrazine in aqueous solution. The isothermal data fitted to Langmuir equation and $Q_m$ was accounted as 0.45mg/g. The bioadsorption processes followed the pseudo- second order rate kinetics. Thus, these results suggested that chemisorption was the underlying mechanism rather than physisorption for dye in order to adsorp on the intersurface of \textit{P. ostreatus}.
