Abstract- In this paper, we address a single machine family scheduling problem where jobs, each characterised by a processing time and an associated positive weight, are partitioned into families and setup time is required between these families. For this problem, we propose a genetic algorithm using an optimised crossover operator designed by an undirected bipartite graph to find an optimal schedule which minimises the total weighted completion time of the jobs in the presence of the sequence independent family setup times. The proposed algorithm finds the best offspring solution among an exponentially large number of potential offspring.

Index Terms- Genetic algorithm, single machine scheduling

I. INTRODUCTION

Genetic algorithms are search algorithms based on the mechanics of natural selection and genetics. They combine survival of the fittest among string structures with a structured yet randomized information exchange to form a search algorithm with some of the innovative flair of human search.

The central theme of research on genetic algorithms has been Robustness, the balance between efficiency and efficacy necessary for survival in many different environments. The normal action of GA is to combine good individuals with characteristics to produce better.

Genetic algorithm optimizers are robust, stochastic search methods modeled on the principles and concepts of natural selection and evaluation.

PRELIMINARIES:

Definition 1
A simple genetic algorithm that yields good results in many practical problems is composed of three operators.

- Reproduction
  Reproduction is a process in which individual strings are copied.

\[
\begin{align*}
100,001,011,000,000 & \rightarrow 100,100,000,011,000 \\
100,100 & \rightarrow 100,001,000,000
\end{align*}
\]

- Crossover
  Crossover is a process of changing one type to the next type.

\[
\begin{align*}
100,100 & \rightarrow 011,001,001 \\
100,100 & \rightarrow 011,000,000
\end{align*}
\]

Mutation
Mutations creates a sudden bit change.

\[
100,100,011,000,000 \rightarrow 100,100,011,000,101
\]

Figure 1

Definition 2
The objective function defining the optimization goal called a fitness function in the GA \( f : c \rightarrow \mathbb{R}^+ \).

The mutation operator provides a means for exploring portions of the solution surface that are not represented in the genetic makeup of the current population.

Figure 2
batches, where ‘1’ means the first job in a batch and ‘0’ means a contiguously sequenced job in a batch. The length of the individual corresponds to the number of jobs N.

**Definition 4**

The fitness function is used to evaluate the individuals which are introduced into the population. We define the fitness function using the property of SWPT (Shortest Weighted Processing Time) rule for batches developed by Mason and Anderson, in which there exists an optimal schedule that the batches appear in SWPT order. As mentioned earlier, a batch is a maximum group of contiguously scheduled jobs within a family. A sequence independent family setup time \( S_f \), is required at the start of the schedule and also whenever there is a switch in processing jobs from one family to jobs of another family.

**Definition 5**

A linear graph \( G = (V,E) \) consists of a set of objects \( V = \{v_1,v_2,\ldots\} \) called vertices and another set \( E = \{e_1,e_2,\ldots\} \), whose elements are called edges. A graph that has neither self-loops nor parallel edges is called a simple graph.

**Definition 6**

A graph \( G \) is called bipartite if its vertex set \( V \) can be decomposed into two disjoint subsets \( V_1 \) and \( V_2 \) such that every edge in \( G \) joins a vertex in \( V_1 \) with a vertex in \( V_2 \).

**Definition 7**

A directed graph \( G \) consists of a set of vertices \( V=\{v_1,v_2,\ldots\} \), a set of edges \( E=\{e_1,e_2,\ldots\} \) and a mapping \( \psi \) that maps every edge onto some ordered pair of vertices \((v_i,v_j)\). As in the case of undirected graphs, a vertex is represented by a point and an edge by a line segment between \( v_i \) and \( v_j \).

**Definition 8**

Any set \( M \) of independent lines of a graph \( G \) is called a matching of \( G \), we say that \( u \) and \( v \) are matched under \( M \). We also say that the points \( u \) and \( v \) are \( M \)-saturated. A matching \( M \) is called a perfect matching if every point of \( G \) is \( M \)-saturated. \( M \) is called a maximum matching if there is no matching \( M' \) in \( G \) such that \( |M'| > |M| \).

**Examples**

Consider the \( G_1 \), \( M_1 = \{v_1v_2, v_6v_3, v_5v_4\} \) is a perfect matching in \( G_1 \). Also \( M_2 = \{v_1v_3, v_9v_5\} \) is a matching in \( G_1 \). However \( M_2 \) is not a perfect matching. The points \( v_2 \) and \( v_4 \) are not \( M_2 \)-saturated. For the \( G_2 \),

\[ M = \{v_4v_5, v_1v_2\} \] is a maximum matching but is not a perfect matching.

**II. Result**

Solution for single machine family scheduling problem by applying Graph theory in GA.

**ALGORITHMIC REPRESENTATION**

According to Aggarwal et al during the optimised crossover scheme, two parents produce two new children. The first child is called the X-child and the second child is called the Y-child. The X-child is constructed in such a way that have the best objective function value from the feasible set of children, while the Y-child is constructed so as to maintain the diversity of the search space. We propose an optimised crossover operator within genetic algorithm for the problem of \( \sum w_i c_i \). The proposed optimised crossover using an directed bipartite graph finds the two new children which are called X-child and Y-child. We will now explain the optimised crossover strategy on
determining the X-child and Y-child for the problem of $1 \mid S \mid \sum w_j c_j$.

Step-1

Identify the parent with the least weight $\sum w_j c_j$ as $P_1$ and select family within the $P_1$, which contains the batch with the largest weighted processing time as family $f$, label another parent as $P_2$. The family $f$ will be used in both $P_1$ and $P_2$.

Step-2

Construct an undirected bipartite graph $G=(U \cup V \cup E)$ where $U=\{u_1, u_2, \ldots, u_n\}$ representing the jobs of family $f$, $V=\{v_1, v_2, v_3, \ldots, v_n\}$ representing bit situation of the jobs of family $f$ in both $P_1$ and $P_2$ (i.e. $v_i \in \{0,1\}$), and $E$ representing the arc set in the graph in which \{u_i, v_i\}, \{u_j, v_i\} $E$ iff job $j$ is represented with the bit situation $v_i$ and $v_i$ respectively.

Step-3

Determine all the maximum matchings in graph $G$. Suppose that there are $K$ jobs of family $f$ that are represented with a different bit situation in the two parents. There will be exactly $2k$ maximum matching’s in graph $G$.

Step-4

Generate a temporary offspring from $P_1$ by replacing the bit situations of the jobs in family $f$ which corresponds to one of the maximum matchings in graph $G$. Repeat the procedure for $2k-1$ times to generate $2k$ temporary offspring. Note that one of the temporary offspring is exactly as $P_1$, thus removed.
